Abstract

We introduce the class MP of languages $L$ which can be solved in polynomial time with the additional information of one bit from a $\#P$ function $f$. We prove that the polynomial hierarchy and the classes $\text{Mod}_k P$, $k \geq 2$, are low for this class. We show that the middle bit of $f(x)$ is as powerful as any other bit, and that a wide range of bits around the middle have the same power. By contrast, the $O(\log n)$ many least significant bits are equivalent to $\oplus P$ [BeGiHe 90], and we show that the $O(\log n)$ many most significant bits are equivalent to PP; hence these bits are probably weaker. We study also the subclass AmpMP of languages whose MP representations can be “amplified,” showing that $\text{BPP}^{\oplus P} \subseteq \text{AmpMP}$, and that important subclasses of AmpMP are low for MP.

We translate some of these results to the area of circuit complexity using MidBit (middle bit) gates. A MidBit gate over $w$ inputs $x_1, \ldots, x_w$ is a gate which outputs the value of the $\lfloor \log(w)/2 \rfloor$th bit in the binary representation of the number $\sum_{i=1}^{w} x_i$. We show that every language in ACC can be computed by a family of depth-2 deterministic circuits of size $2^{\log n^c}$ with a MidBit gate at the root and AND-gates of fan-in $(\log n)^c$ at the leaves. This result improves the known upper bounds for the class ACC.
1 Introduction

The complexity classes PP (probabilistic polynomial time [Gi 77]) and \( \oplus P \) (parity P, [PaZa 83, GoPa 86]) have received much attention since the well known result by Toda [Tod 89] proving that the polynomial time hierarchy (PH) is Turing reducible to PP. These classes are closely related to the class of counting functions \( \# P \) [Va 79] that count the number of accepting paths on nondeterministic Turing machines. Observe that sets in PP and \( \oplus P \) can be respectively decided with the information of the leftmost and rightmost bit of a \( \# P \) function. Toda's proof combines two important results; on one side he shows that PH is randomly reducible to \( \oplus P \), and in a second part he proves that PP is included in \( \oplus P \). A careful observation of the proof of the last result shows that for this inclusion the whole power of \( \oplus P \) is not needed. To decide an input \( x \), a function \( f \in \# P \) has to be queried just once, and more interestingly, just one bit of information of \( f \) is needed, as in the case of PP or \( \oplus P \). It is natural to ask what other problems can be computed by looking at just one bit of a \( \# P \) function.

We consider the complexity class MP of languages that can be decided with the help of any one selected bit. This class is a natural generalization of both PP and \( \oplus P \), and seems easier than the much-studied class \( P^{\# P} \). We suppose that the values of a \( \# P \) function \( f(x) \) are encoded as binary numbers, with the least significant bits indexed first (the index of the least significant bit being 0).

**Definition 1.1** A language \( L \) is in MP if there exists a function \( f \) in \( \# P \) and a function \( g \) in \( FP \) (called a bit selection function) such that for all \( x \), \( x \) is in \( L \) if and only if there is a 1 at position \( g(x) \) in the binary representation of \( f(x) \).

That is, for all \( x \), \( x \in L \iff [f(x)/2^{g(x)}] \mod 2 = 1 \). The 'M' stands for "middle bit", since we show that wlog \( g \) can be the function which indexes the middle bit of the binary representation of \( f(x) \).

We investigate in Section 3 the basic properties of MP. It is known that the rightmost \( O(\log n) \) bits of a \( \# P \) function still give the power of \( \oplus P \) [BeGiHe 90]; we show that the leftmost \( O(\log n) \) bits do likewise for PP. MP is closed downward under polynomial time many-one reducibility and has complete problems. The problem of whether MP is closed under intersection leads to a question of general mathematical interest about the size of integer-valued polynomials which satisfy certain congruence equations. We discuss this question at the end of the section.

In Section 4 we consider subclasses of MP that correspond to special kinds of \( \# P \) functions, having many zeroes around the deciding bit. We show that these classes are low for MP. Although those \( \# P \) functions have a very special form, important classes like the polynomial hierarchy (PH) and \( \oplus P \) do have such a representation. The class of all languages that fulfill this 'amplification condition' will be called AmpMP. We give closure
properties of AmpMP and show that important subclasses of this class including BPP and PH are low for AmpMP and for MP. If AmpMP = MP, or even if $C_m \subseteq$ AmpMP, then the counting hierarchy [Wa 86] collapses to MP.

Definition 1.1 makes sense even when $f(x)$ is written in base $k$, $k \geq 3$, rather than base 2, and it is natural to ask whether the class defined remains the same. On one hand, the classes Mod$k$P analogous to $\oplus P$ for the least significant bit are all believed to be different. On the other hand, the "most significant bit = 1" definition of PP yields the same class in any base, since PP is closed under Booleans [BeReSp 91]. We had hoped to show that if MP is closed under intersection then its definition is independent of the base, but are unable to do so in this paper. While it is immediate that $\oplus P \subseteq$ MP it is not so obvious whether Mod$k$P $\subseteq$ MP since in order to decide whether a number written in base 2 is congruent to 0 modulo 3, one needs the information of each one of its bits.

By constructing suitable #P functions we prove however in Section 5 that for each $k$ the class Mod$k$P [BeGiHe 90] is included in MP. In fact, we show that for every $k$, Mod$k$P is in AmpMP and therefore is low for MP.

In Section 6 we give an application of the previous results improving the known upper bound for the circuit class ACC. This class was defined by Barrington [Ba 89] as the class of languages accepted by bounded depth polynomial size circuits with AND, OR, NOT and a finite set of Mod$k$ gates. Clearly ACC contains AC$^0$ and is contained in TC$^0$. Since the PARITY function cannot be computed in AC$^0$ the first inclusion is proper. Barrington [Ba 89] conjectured that the second inclusion is also proper i.e., TC$^0 \nsubseteq$ ACC, but no proof of this fact has been obtained.

Using Toda's result [Tod 89] and building on some work on AC$^0$ by Allender and Hertrampf [Al 89], [AlHe 90], Yao [Yao 90] proved the first non-trivial upper bound for ACC. He showed that every language in ACC is recognized by a family of depth-2 probabilistic circuits of size $2^{(\log n)^c}$ with a symmetric gate at the root and AND-gates of fan-in $(\log n)^c$ at the leaves. Recently Beigel and Tari [BeTa 91] have improved this result showing that the circuits given by Yao can be made deterministic without increasing their size. However in both cases the symmetric gate at the root depends on the type of the modular gates used in the ACC circuit. It is therefore very hard to prove that a certain function cannot be computed by depth-2 circuits of the type given in [Yao 90] or [BeTa 91] since all that can be said about the gates in the root is that they belong to an infinite subfamily of the symmetric functions. We improve the above upper bounds showing that the mentioned circuits can be restricted to have a symmetric gate of type MidBit at the root. A MidBit gate over $w$ inputs $x_1, \ldots, x_w$ is a gate which outputs the value of the $[\log(w)/2]$th bit in the binary representation of the number $\sum_{i=1}^{w} x_i$. We prove that ACC can be computed by a family of depth-2 deterministic circuits of size $2^{(\log n)^c}$ with a MidBit gate at the root and AND-gates of fan-in $(\log n)^c$ at the leaves. We believe that there are TC$^0$ languages
which cannot be computed by circuits of this kind, and that the study of these circuits can therefore provide a way to show that $\text{TC}_0$ is not contained in $\text{ACC}$.

2 Preliminaries and Notation

All languages considered here are over the alphabet $\Sigma = \{0, 1\}$. The length of a string $x \in \Sigma^*$ is denoted by $|x|$. If $n$ is a natural number, $|n|$ denotes the length of its binary encoding, namely $|n| = \lceil \log_2(n) \rceil + 1$. We assume the existence of a pairing function $\langle \cdot, \cdot \rangle : \Sigma^* \times \Sigma^* \to \Sigma^*$ that is computable in polynomial time and has inverses also computable in polynomial time. For a set $A$, $|A|$ denotes its cardinality. The characteristic function of a set $A$ is denoted by $\chi_A$.

We assume that the reader is familiar with (nondeterministic, polynomial time bounded, oracle) Turing machines and complexity classes (see [BaDiGa 87, Schö 86]). $\text{FP}$ is the class of functions computable by a deterministic polynomial time bounded Turing transducer.

The class of functions computable by a deterministic polynomial time bounded oracle Turing transducer asking parallel queries to a (set or function) oracle in $\mathcal{C}$ is denoted by $\text{FP}_{\mathcal{C}}^\parallel$.

An $\text{NP}$ machine is a nondeterministic polynomial time bounded Turing machine $M$ that on every computation path either accepts or rejects. The number of all accepting computation paths of $M$ on input $x$ is denoted by $\#\text{acc}_M(x)$. A set $L$ is said to be in the class $\text{PP}$ if there exists an $\text{NP}$ machine $M$ whose run-time is bounded by polynomial $p$, such that for any $x$, $x \in L$ iff $\#\text{acc}_M(x) > 2^{p(|x|)-1}$. A set $L$ is in $\oplus \text{P}$ if there exists an $\text{NP}$ machine $M$ such that for any $x$, $x \in L$ iff $\#\text{acc}_M(x)$ is odd. For any natural number $k > 2$ the class $\text{Mod}_k \text{P}$ is similarly defined except that $x \in L$ iff $\#\text{acc}_M(x) \not\equiv 0 \pmod{k}$.

For a relativizable language class $\mathcal{C}$, $\mathcal{C}^{\mathcal{B}[k]}$ is the class of all sets in $\mathcal{C}^\mathcal{B}$ witnessed by a machine of type $\mathcal{C}$ asking at most $k$ queries on every computation path.

Let $\leq_\alpha$ be any reducibility. The reduction class $\{A \mid \exists B \in \mathcal{C} : A \leq_\alpha B\}$ of all sets $\leq_\alpha$-reducible to some set in $\mathcal{C}$ is denoted by $R_\alpha(\mathcal{C})$.

3 Counting Classes and Bits of $\#\text{P}$ Functions

As indicated above, $(\text{PP} \cup \oplus \text{P}) \subseteq \text{MP}$. In fact,

Proposition 3.1

(a) $\text{PP}^{\oplus \text{P}} \subseteq \text{MP} \subseteq P^{\#\text{P}[1]}$.

(b) $\text{MP}$ is closed under complementation.

(c) $\text{MP}$ has complete sets under $\leq_\text{P}^\text{R}$, and is closed under this reducibility.
Proof. (a) The inclusion PP \subseteq MP follows from inspection of Toda's proof [Tod 89] that PP \subseteq P^\#P. The inclusion MP \subseteq P^\#P[1] is obvious.

(b) Let \( f \) be a \#P function and let \( g \in \text{FP} \) be a bit selection function witnessing \( L \in \text{MP} \). Consider the \#P function \( h(x) = f(x) + 2^x(x) \). Since there is a 1 at position \( g(x) \) in the binary representation of \( f(x) \) if and only if there is a 0 at position \( g(x) \) in the binary representation of \( h(x) \), it follows that \( L \in \text{MP} \).

(c) The language \( U_{\text{MP}} = \{ (N, x, 0^k, 0^n) \mid N \text{ is a nondeterministic TM and there is a 1 at position } k \text{ in the binary representation of the number of all accepting paths of length } \leq m \text{ of } N \text{ on input } x \} \) can easily be seen to be complete for MP under \( \leq^P_m \). Now let \( B \) be in MP via some \#P function \( f \) and bit selection function \( g \in \text{FP} \), and suppose that \( A \leq^P_m B \) via some FP function \( h \). Then \( f \circ h \) is in \#P and \( f \circ h \) is in FP, and it holds for all \( x \in \Sigma^* \) that \( x \in A \) if and only if there is a 1 at position \( g(h(x)) \) in the binary representation of \( f(h(x)) \), i.e. \( A \in \text{MP} \).

\[ \square \]

Theorem 3.2 Let \( L \) be in MP via a function \( f \in \#P \) and a bit selection function \( g \in \text{FP} \).

(a) [BeGiHe 90] If \( g(x) = O(\log(|x|)) \), then \( L \in \text{PP} \).

(b) If \( |f(x)| - g(x) = O(\log(|x|)) \), then \( L \in \text{PP} \).

Proof. (b) Let \( c \) be a constant such that \( |f(x)| - g(x) \leq c \log(|x|) \) for all \( x \in \Sigma^* \). Then \( f(x) < 2^{|x|} + c \log(|x|) \), and the bits at the positions \( g(x) + c \log(|x|) - 1, \ldots, g(x) \) in the binary representation of \( f(x) \) can be computed in polynomial time by binary search asking \( c \log(|x|) \) many queries to the PP oracle set \( \{ (x, i) \mid f(x) \geq i \} \). This shows that \( L \in P^{PP}[O(\log n)] \), which equals PP [BeReSp 91]. \[ \square \]

The previous theorem shows that the bits at either end are weak. However it is easy to see that the bit in the middle, together with a wide range of bits around it, are strong.

Proposition 3.3 (a) Let \( L \in \text{MP} \). Then there is a \#P function \( f \) such that for all \( x \), \( |f(x)| \) is odd, and \( x \in L \) iff the middle bit of \( f(x) \) is a 1.

(b) Let \( L \in \text{MP} \), and let \( \epsilon, \delta > 0 \) and \( k \geq 1 \) be fixed. Let \( g_p \) be a bit-selection function which takes a polynomial \( p \) as a parameter, such that for all inputs \( x \), with \( n := |x| \), \( p(n) \delta/n^k < g_p(x) < (1 - \epsilon/n^k)p(n) \). Then there is a \#P function \( f \) and a bounding polynomial \( p \) for \( f \) such that \( L \in \text{MP} \) via \( f \) and \( g_p \).

Proof. (a) Let the NTM \( M \), polynomial \( p \), and bit-selection function \( g \in \text{FP} \) be such that \( L \in \text{MP} \) via \( f \) and \( g \), and for all \( x \), \( \#acc_M(x) < 2^{|p(x)|} \). Then let \( M' \) be an NTM which on any input \( x \) first calculates \( d := p(|x|) - g(x) \), makes \( d \)-many dummy nondeterministic
moves, and then simulates $M(x)$. This multiplies the number of accepting computations of $M(x)$ by $2^d$, and thus moves bit $g(x)$ of $\#\text{acc}_M(x)$ to position $p(|x|)$. Now build an NTM $M''$ such that for all $x$, $\#\text{acc}_{M''}(x) = \#\text{acc}_M(x) + 2^{p(|x|)}$, and let $f(x) := \#\text{acc}_{M''}(x)$. Then $f$ has the desired property. Part (b) is proved by similar “bit-shifting” methods. □

Define a bit-query machine to be a machine which takes a function $f$ as oracle and makes queries of the form $(y, i)$, receiving bit $i$ of $f(y)$ from the oracle. Since $\text{MP} \subseteq \text{P}^{\text{PP}}$, the leftmost bit can be used as an oracle for the middle bit. That is, for every $L \in \text{MP}$ there is a polynomial-time bit-query machine $M$, a $\#P$ function $f$, and a polynomial $p$ which bounds the lengths of values of $f$, such that $M$ makes queries of the form $(y, p(|y|))$ and accepts $L$ with oracle $f$. On the other hand, the rightmost bit probably cannot be used as an oracle for the middle bit, since $\text{P}^{\text{PP}} = \oplus \text{P}$ and $\text{MP}$ is unlikely to be contained in $\oplus \text{P}$. The next result extends the range to the right of bits which can be used as oracles for the middle bit.

**Proposition 3.4** Let $L \in \text{MP}$, let $\delta > 0$ and $k \geq 1$ be fixed, and let $g \in \text{FP}$ be such that for all $y$, $g(y) > \delta |y|^{1/k}$. Then there is a polynomial-time machine $M$ with oracle function $f \in \#P$ such that on any input $x$, $M(x)$ makes one bit query $(y, g(y))$, and accepts iff the bit returned is a 1.

**Proof.** The string $y$ has the form $0^m 1_x$, where $m := \lceil |x|^{1/k} \rceil - |x| - 1$. The remaining details are similar to those of Proposition 3.3 and are left to the reader. □

The proof gives a many-one reduction; we do not know whether a Turing reduction could use lower-order bits. Nor do we know more about the power of bits $g(y)$ for functions $g$ which are $\omega(|\log |y|)|y|$ and $o(|y|^{1/\epsilon})$ for all $\epsilon > 0$.

Since a bit-query machine with a $\#P$ function as oracle can always be simulated by a standard oracle TM with an MP language as oracle, and vice-versa, we revert to the standard formalism in assessing the power of the number of bit-queries to a $\#P$ function:

**Theorem 3.5**

(a) $P^{\text{MP}[1]} = \text{MP}$.

(b) $\text{MP}$ is closed under intersection if and only if $\text{MP} = \bigcup_{k \geq 1} P^{\text{MP}[k]}$.

**Proof.** (a) It is easy to see that $\text{MP}$ is closed under join. By Proposition 3.1, $\text{MP}$ is also closed under $\leq_L \text{P}$ and under complementation, and thus it follows that $\text{MP}$ is closed under $\leq_{\text{ttf}} \text{P}$, i.e. $P^{\text{MP}[1]} = \text{MP}$.

(b) Since $\text{MP}$ contains $\text{P}$ and is closed under polynomial time many-one reductions, it follows that the bounded truth-table closure of $\text{MP}$ (which is easily seen to be $\bigcup_{k \geq 1} P^{\text{MP}[k]}$)

5
coincides with the Boolean closure of MP [KöScWa 87]. Now, since MP is closed under complementation, if MP is also closed under intersection then the Boolean closure of MP equals MP.

Proposition 3.6

(a) $P_{MP} = P_{PP} = P_{\#P}$.

(b) $FP_{MP} = FP_{\#P}$

(c) The closure of MP under polynomial time tt-reductions equals $P_{\#P}[1]$.

Proof. (a) is obvious.

(b) follows from the fact that the value of a $\#P$ function can be computed in polynomial time by asking parallel queries to an MP oracle.

(c) Since $P_{\#P}[1]$ is closed under polynomial time tt-reductions [CaHe 89], it follows that $R_{tt}(MP) \subseteq R_{tt}(P_{\#P}[1]) = P_{\#P}[1]$. The converse inclusion follows from (b).

There are two unresolved structural properties of the class MP which seem both important and amenable to attack. The first is the problem of whether MP is closed under intersection. The direct attempt to solve this by writing and solving equations leads to the following purely numerical question, which we have circulated among mathematicians. (Say $x$ is top modulo $2^k$ if $x \mod 2^k \geq 2^{k-1}$.)

In terms of $k$, what is the minimum degree of an integer-valued polynomial $p(x, y)$ such that for some polynomial $t$ and for all $x, y$ it is true that $p(x, y)$ is top modulo $2^{t(k)}$ \iff both $x$ and $y$ are top modulo $2^k$?

The simplest polynomial we know which satisfies this congruence relation is $p(x, y) := (2^{k-1}(2^{k-1})y^k - 1$. Smaller ones have been found by A. Odlyzko and M. Coster [personal communication, 1991], but they still have exponential degree and coefficient size. If such $p$ can be found with degree polynomial in $k$, then $p$ can be written as a polynomial-sized sum of small binomial coefficients in $x$ and $y$, which can then be used in building polynomial-time NTMs. Then it would follow, after "lining-up" decision bits, that MP is closed under intersection. A similar congruence relation modulo $2^k$ with the same open problem is $p(x, y) = 0 \iff (x = 0 \land y = 0)$.

The second open problem concerns whether the inclusions in Proposition 3.1(a) are proper. It is not even known whether there is an oracle separating $PP^{\#P}$ from $P_{\#P}[1]$ or even from PSPACE. Since $PP^{\#P}$ is closed under polynomial-time truth-table reductions, as follows by relativizing the proof for PP in [FoRe 91], MP = $PP^{\#P}$ implies that both classes are equal to $P_{\#P}[1]$. 

6
4 The Class AmpMP

Toda’s proof, which as mentioned in Prop. 3.1(a) yields $PP^{\#P} \subseteq MP$, actually shows that languages $L$ in $PP^{\#P}$ have $MP$-representations of a special kind. Namely, there is a $\#P$ function $f$ such that for any input $x$ and number $m$, not only does the middle bit of $f(x, 0^m)$ equal ‘1’ iff $x \in L$, but also the $m$ bits to the left of this bit are always ‘0’. We call this property “amplification on the left of the decision bit.” Technically, $(x, 0^m)$ stands for the string $x10^m$, and the point is that $m$ can be made as large as desired. In this section we study the stronger notion of “amplification on both sides of the decision bit,” which leads to the class AmpMP formalized as follows:

**Definition 4.1** A language $L$ is in AmpMP if there are a polynomial $p$ and a $\#P$ function $f$ such that for every $x \in \Sigma^*$ and $m > 0$, $f(x, 0^m)$ is of the form

$$f(x, 0^m) = a(x, 0^m)2^{p(n)+2m+1} + x_L(x)2^{p(m)+m} + b(x, 0^m)$$

where $n = |x| + m$ and $b(x, 0^m) < 2^{p(n)}$.

In other words, $L$ is in AmpMP if there are polynomials $p, r$ and a $\#P$ function $f$ such that for every $x \in \Sigma^*$ and $m > 0$, the binary representation of $f(x, 0^m)$ is of the form

$$a_{r(n)} \ldots a_0 0 \ldots 0 x_L(x) 0 \ldots 0 b_{p(n)-1} \ldots b_0$$

where $b_0, \ldots, b_{p(n)-1}, a_0, \ldots, a_{r(n)} \in \{0, 1\}$. The next lemma shows that the class AmpMP is very robust, and closed under Boolean operations.

**Lemma 4.2**

(a) AmpMP is closed under complementation,

(b) AmpMP is closed under intersection,

(c) AmpMP is closed under bounded truth table reductions.

**Proof.** (a) Let $L$ be in AmpMP. We have to show that there are a polynomial $p$ and a $\#P$ function $h$ fulfilling the condition in the definition of AmpMP for the complement of $L$. Since $L$ is in AmpMP there are a polynomial $p$ and a $\#P$ function $f$ such that for every $x \in \Sigma^*$ and $m > 0$, the binary representation of $f(x, 0^m)$ is of the form

$$a_{r(n)} \ldots a_0 0 \ldots 0 x_L(x) 0 \ldots 0 b_{p(n)-1} \ldots b_0$$

where $n = |x| + m$. Consider the following function $f'(x, 0^m)$ whose value in binary is

$$a_{r(n)} \ldots a_0 1 \ldots 1 x_L(x) 1 \ldots 1 b_{p(n)-1} \ldots b_0$$

7
Clearly, $f' \in \#P$, and there are a polynomial $t$ and an NP machine $M$ having on input $(x, 0^m)$ exactly $2^{t(n)}$ different computation paths such that $\#acc_{M}(x, 0^m) = f'(x, 0^m) + 1$. Now the desired $\#P$ function $h$ can be obtained by inverting $f'$ bitwise, i.e. $h(x, 0^m) = 2^{t(n)} - f'(x, 0^m) = \#acc_{\overline{M}}(x, 0^m)$, where $M$ is obtained from $\overline{M}$ by interchanging accepting and rejecting states.

(b) Let $A, B$ be two sets in AmpMP. We have to show that there are a polynomial $p$ and a $\#P$ function $h$ fulfilling the condition in the definition of AmpMP for the set $A \cap B$. Since $A, B$ are in AmpMP, there are polynomials $p_A, p_B, t$ and $\#P$ functions $h_A, h_B$ such that $t(n) \geq p_A(n) + 2m$ (letting $n = |x| + m$) and

$$h_A(x, 0^m) = a(x, 0^m)2^{p_A(n)+2m+1} + \chi_A(x)2^{p_A(n)+m} + b(x, 0^m) < 2^{t(n)}$$

where $b(x, 0^m) < 2^{p_A(n)}$, and

$$h_B(x, 0^m) = a'(x, 0^m)2^{p_B(n)+2m+1} + \chi_B(x)2^{p_B(n)+m} + b'(x, 0^m)$$

where $b'(x, 0^m) < 2^{p_B(n)}$. Now define $h(x, 0^m) = h_A(x, 0^m) \cdot h_B(x, 0^m)$, then

$$h(x, 0^m) = \left[a'(x, 0^t(n))2^{p_B(n)+2t(n)+1} + \chi_B(x)2^{p_B(n)+t(n)} + b'(x, 0^t(n))\right] \cdot h_A(x, 0^m)$$

$$= a''(x, 0^m)2^{p_A(n)+p_B(n)+t(n)+2m+1} + \chi_A \land B(x)2^{p_A(n)+p_B(n)+t(n)+m} + b''(x, 0^m)$$

where $b''(x, 0^m) = \chi_B(x)2^{p_B(n)+t(n)}b(x, 0^m) + b'(x, 0^t(n))h_A(x, 0^m) < 2^{p_A(n)+p_B(n)+t(n)}$, and $a''(x, 0^m) = a'(x, 0^t(n))2^{p_A(n)-2m}h_A(x, 0^m) + \chi_B(x)a(x, 0^m)$.

(c) We first show that AmpMP is closed under many-one reductions. Let $B$ be in AmpMP, and suppose that $A \leq_p B$ via some FP function $g$. Since $B$ is in AmpMP there are a polynomial $p$ and a $\#P$ function $f$ such that for every $x \in \Sigma^*$ and $m > 0$, the binary representation of $f(x, 0^m)$ is of the form

$$f(x, 0^m) = a(x, 0^m)2^{p(n)+2m+1} + \chi_B(x)2^{p(n)+m} + b(x, 0^m)$$

where $n = |x| + m$ and $b(x, 0^m) < 2^{p(n)}$. Consider the function $f'(x, 0^m) = f(g(x), 0^m)$ which is of the form

$$f'(x, 0^m) = a(g(x), 0^m)2^{p(n)+2m+1} + \chi_A(x)2^{p(n)+m} + b(g(x), 0^m)$$

where $n = |g(x)| + m$ and $b(g(x), 0^m) < 2^{p(n)}$. Let $q$ be a polynomial such that $q(|x| + m) \geq p(|g(x)| + m)$. Then the $\#P$ function $f''(x, 0^m) = f'(x, 0^m) \cdot 2^{t(|x|+m)} \cdot p(|g(x)|+m)$ and the polynomial $q$ form an AmpMP representation for $A$.

Since AmpMP contains P and is closed under many-one reductions it follows that the bounded truth-table closure of AmpMP coincides with the Boolean closure of
AmpMP [KöScWa 87]. This completes the proof because (a) and (b) AmpMP is closed under Boolean operations.

It is an open problem whether AmpMP is closed under conjunctive reductions. As we will see this problem is related to the lowness properties of the class. The concept of lowness in the context of computational complexity theory was first introduced by Schöning [Sch 83] and was first studied in counting classes by Torán [Tor 88]. A class \( \mathcal{A} \) is low for a relativizable complexity class \( \mathcal{C} \) if the sets in \( \mathcal{A} \), when used as an oracle for \( \mathcal{C} \), do not help, i.e., \( \mathcal{C}^\mathcal{A} = \mathcal{C} \).

We would like to prove that AmpMP is low for the class MP. This would happen if AmpMP were closed under conjunctive polynomial time reducibility. We can prove however a series of lowness results which are based on the following theorem.

**Theorem 4.3** Let \( k \) be a constant. For every function \( f \in \#P^{AmpMP[k]} \) there are a function \( g \in \#P \) and a polynomial \( p \) such that for every \( x \in \Sigma^* \) and \( m > 0 \),

\[
f(x) \equiv |g(x, 0^m)|2^{p(|x|+m)} \pmod{2^m}.
\]

**Proof.** Since AmpMP is closed under bounded truth table reductions there is a language \( A \in \text{AmpMP} \) and a polynomial \( q \) such that

\[
f(x) = \sum_{y \in \Sigma^*} \chi_A(x, y)
\]

Because of \( A \in \text{AmpMP} \) there are a polynomial \( r \) and a \( \#P \) function \( h \) such that for every \( x \in \Sigma^* \) and \( m > 0 \), \( h(x, y, 0^m) \) is of the form

\[
h(x, y, 0^m) = a(x, y, 0^m)2^{r(n)+2m+1} + \chi_A(x, y)2^{r(n)+m} + b(x, y, 0^m)
\]

where \( n = |x| + m \) and \( b(x, y, 0^m) < 2^{r(n)} \). Now the proof of the theorem is completed by choosing the polynomial \( p(n) \geq r(n) + q(|x|) + m \) and defining \( g(x, 0^m) = \sum_{y \in \Sigma^*} h(x, y, 0^{m+q(|x|)})2^{p(n)-r(n)-q(|x|)-m} \).

Note that Theorem 4.3 even allows us to isolate the binary representation of \( f(x) \) inside the binary representation of some \( \#P \) function \( h(x, 0^m) \) by \( m \) 0's to the left and to the right, i.e., \( h(x, 0^m) \) is of the form

\[
a_{r(n)} \ldots a_0 \underbrace{0 \ldots 0}_{m \text{ times}} \underbrace{bin(f(x)) \ldots 0}_{m \text{ times}} b_{p(n)-1} \ldots b_0
\]

where \( n = |x| + m \), \( p, r \) are polynomials, \( b_0, \ldots, b_{p(n)-1}, a_0, \ldots, a_{r(n)} \in \{0, 1\} \), and \( bin(f(x)) \in \Sigma^t(|x|) \) is the binary representation of \( f(x) \) (possibly with leading 0's) for some polynomial \( t \). To see this, first define \( f'(x, 0^m) = f(x) \cdot 2^m \) and apply Theorem 4.3 to get a function \( h(x, 0^m) \) such that \( f'(x, 0^m) \equiv [h(x, 0^m)]2^{p(|x|+m)} \pmod{2^{t(|x|)+2m}} \).

Now we are ready to state our first "lowness" result.
Corollary 4.4

1. $\bigcup_{k>1} \text{MP}^{\text{AmpMP}[k]} = \text{MP}$

2. $\bigcup_{k>1} \text{AmpMP}^{\text{AmpMP}[k]} = \text{AmpMP}$

Proof. By Theorem 4.3 it follows that for every function $f \in \#P^{\text{AmpMP}[k]}$ there exist a function $g \in \#P$ and a polynomial $t$ such that the binary representation of $f(x)$ is reproduced inside the binary representation of $g(x, 0^{t(|x|)})$. The rest is clear. \qed

Corollary 4.5 Let $C$ be a subclass of AmpMP. If $C$ is closed under conjunctive and disjunctive reducibilities then $C$ is low for MP and for AmpMP.

Proof. This is a direct consequence of Corollary 4.4 since if $C$ is closed under conjunctive and disjunctive reducibilities then it is easy to see that $\text{MP}^C = \text{MP}^{C[2]}$ and $\text{AmpMP}^C = \text{AmpMP}^{C[2]}$. \qed

Corollary 4.6 If $C_{_{mP}} \subseteq \text{AmpMP}$ then $\text{CH} = \text{MP}$.

Proof. Assume that $C_{_{mP}} \subseteq \text{AmpMP}$. Since the class $C_{_{mP}}$ is closed under disjunctive and conjunctive reductions ([Tor 88],[Gr 91],[BeChOg 91]) it follows by Corollary 4.5 that $C_{_{mP}}$ is low for MP. Now the collapse of the counting hierarchy follows easily using the equality $\text{MP}^{C_{_{mP}}} = \text{MP}^{C_{_{mP}}[2]}$ [Tor 88]. \qed

We show now that several important complexity classes are included in AmpMP. It will follow from the next result proved by Toda [Tod 89] that $\oplus P$ is contained in AmpMP (even in the subclass of AmpMP where $p(n) = 0$).

Theorem 4.7 [Tod 89] For every language $A \in \oplus P$ there exists a $\#P$ function $h$ such that $h(x, 0^m) \equiv \chi_A(x) \pmod{2^m}$.

Corollary 4.8 $\oplus P$ is contained in AmpMP and therefore $\oplus P$ is low for MP and AmpMP.

Proof. Let $A$ be in $\oplus P$. By Theorem 4.7 there is a function $h \in \#P$ such that $h(x, 0^m) \equiv \chi_A(x) \pmod{2^{m+1}}$. Then also the function $f(x, 0^m) = h(x, 0^m) \cdot 2^m$ is in $\#P$, witnessing $A \in \text{AmpMP}$. The lowness follows by Corollary 4.5 since $\oplus P$ is closed under Turing reductions [PaZa 83]. \qed

The next corollary states that for every function $f$ in $\#P^{\oplus P}$ there is a function $g \in \#P$ such that $f(x)$ and $g(x, 0^m)$ agree in the last $m$ bits.
Corollary 4.9 For every function \( f \) in \( \#P^{\oplus P} \) there exists a function \( g \) in \( \#P \) such that

\[
g(x, 0^m) \equiv f(x) \pmod{2^m}.
\]

Proof. Let \( f \) be in \( \#P^{\oplus P} \). Since \( \oplus P \) is closed under Turing reductions [PaZa 83] there exist a language \( A \) in \( \oplus P \) and a polynomial \( q \) such that

\[
f(x) = \sum_{y \in \Sigma^* | x|} \chi_A(x, y)
\]

By Theorem 4.7 there is a function \( h \in \#P \) such that \( h(x, y, 0^m) \equiv \chi_A(x, y) \pmod{2^m} \).

Now the corollary follows defining \( g(x, 0^m) = \sum_{y \in \Sigma^* | x|} h(x, y, 0^m) \).

As a consequence of the next theorem we will get the containment of BPP in AmpMP (even in the subclass of AmpMP where \( a(x, 0^m) = 0 \)).

Theorem 4.10 For every language \( L \in \text{BPP} \) there exist a polynomial \( t \) and a function \( h \in \#P \) such that

\[
\chi_L(x) \cdot 2^m = \lfloor h(x, 0^m) / 2^{t(n) - m} \rfloor
\]

where \( n = |x| + m \).

Proof. Let \( L \) be in BPP. By the probability amplification lemma for BPP, there exists a function \( h \in \#P \) and a polynomial \( t \) such that

\[
x \in L \Rightarrow h(x, 0^m) \geq 2^{t(n)} - 2^{t(n) - m - 2} \]

\[
x \notin L \Rightarrow h(x, 0^m) \leq 2^{t(n) - m - 2}
\]

and therefore \( h \) fulfills the following inequalities,

\[
\chi_L(x, 0^m)2^{t(n)} - 2^{t(n) - m - 2} \leq h(x, 0^m) \leq \chi_L(x, 0^m)2^{t(n)} + 2^{t(n) - m - 2}
\]

Because \( \#P \) is closed under addition, the proof can be completed by defining \( h(x, 0^m) = h(x, 0^m) + 2^{t(n) - m - 2} \) since \( h \) fulfills the inequalities

\[
\chi_L(x, 0^m)2^{t(n)} \leq h(x, 0^m) \leq \chi_L(x, 0^m)2^{t(n)} + 2^{t(n) - m - 1}
\]

Corollary 4.11 BPP is contained in AmpMP and therefore is low for MP and AmpMP.
Proof. The containment of BPP in AmpMP follows immediately from Theorem 4.10, and the lowness follows by Corollary 4.5 since BPP is closed under Turing reductions. □

The next corollary states that for every function $f \in \#P^{\text{BPP}}$ and every polynomial $p$ there is a function $g \in \#P$ such that $f(x)$ and $g(x)$ agree in the leftmost $p(|x|)$ many bits where the leftmost bit of a binary number is the most significant bit which is 1.

**Corollary 4.12** For every function $f \in \#P^{\text{BPP}}$ there exist a polynomial $r$ and a function $g \in \#P$ such that

$$f(x) = \lfloor g(x)/2^{r(|x|)} \rfloor$$

Proof. Let $f$ be in $\#P^{\text{BPP}}$. Since BPP is closed under Turing reductions there exist a language $L$ in BPP and a polynomial $q$ such that

$$f(x) = \sum_{y \in \Sigma^{|x|}} \chi_L(x, y)$$

By Theorem 4.10 there is a $\#P$ function $h$ and a polynomial $t$ such that

$$\chi_L(x, y) \cdot 2^m = \lfloor h(x, y, 0^m)/2^{t(|x|+m)-m} \rfloor$$

Defining the $\#P$ function $g$ as

$$g(x) = \sum_{y \in \Sigma^{|x|}} h(x, y, 0^q(|x|))$$

it follows that

$$\lfloor g(x)/2^{r(|x|+q(|x|))} \rfloor = f(x)$$

which completes the proof if we choose $r(n) = t(n+q(n))$. □

**Corollary 4.13** $\text{BPP}^{\text{NP}}$ and the polynomial hierarchy PH are low for both MP and AmpMP.

Proof. Since $\text{BPP}^{\text{NP}}$ is closed under Turing reductions, it suffices by Corollary 4.5 to show that it is contained in AmpMP. This follows by relativizing Corollary 4.11 to $\oplus \text{P}$ and observing $\text{AmpMP}^{\text{NP}} \subseteq \text{AmpMP}$ by Corollary 4.8. The lowness of PH follows since $\text{PH} \subseteq \text{BPP}^{\text{NP}}$. □

Using relativized versions of Theorems 4.12 and 4.9, we get the following theorem which is stronger than what we would get by Theorem 4.3 because the polynomial $p$ only depends on $|x|$ and not on $m$.  

12
Theorem 4.14 For every function $f$ in $\#P_{\text{pp}}$ there are a function $g \in \#P$ and a polynomial $p$ such that
\[
f(x) \equiv \lfloor g(x, 0^m)/2^{p(|x|)} \rfloor \pmod{2^m}.
\]

Proof. Let $f$ be in $\#P_{\text{pp}}$. Since Corollary 4.12 relativizes, there exists a polynomial $p$ and a function $h \in \#P_{\text{pp}}$ such that
\[
f(x) = \lfloor h(x)/2^{p(|x|)} \rfloor
\]
By Theorem 4.9, there exists a function $g \in \#P$ such that
\[
g(x, 0^m) \equiv h(x) \pmod{2^{m+p(|x|)}},
\]
and therefore
\[
\lfloor g(x, 0^m)/2^{p(|x|)} \rfloor \equiv f(x) \pmod{2^m}.
\]

\[\square\]

5 Lowness of Mod Classes for the Class MP

In this section we show that for any $k$, Mod$_k$P is included in AmpMP, thereby proving that Mod$_k$P is low for MP and AmpMP.

The key to this result is the following lemma, which says that the “amplification” of a $\#P$-function in $k$-adic representation can, in some sense, be saved in dyadic representation.

Lemma 5.1 Let $r, q$ be polynomials.

If $f \in \#P$ is of the form $f(x) = a(x)k^{r(|x|)} + b(x)$, where
\[
b(x) < \frac{k^{r(|x|)}}{2^q(|x|)+2},
\]
then there exist a function $h$ in $\#P$ and a polynomial $p$ such that
\[
h(x) = a'(x)2^{p(|x|)+q(|x|)} + b(x)2^{p(|x|)} + c(x),
\]
where $c(x) < 2^{p(|x|)}$ and $a'(x)$ is a multiple of $a(x)$.

Proof. Since $f$ is in $\#P$ there exists a polynomial $s$ such that $f(x) < 2^{s(|x|)}$ for all $x$. We first prove the following claim.

Claim. There exist a polynomial $p$ and a function $g$ in $\#P$ such that
\[
g(x) = a(x)2^{p(|x|)} + b'(x) \quad \text{and} \quad b'(x) < 2^{p(|x|)-q(|x|)-1}.
\]

13
Proof of Claim. Define
\[ g(x) = f(x) \left\lceil \frac{2^{p(|x|)}}{k^r(|x|)} \right\rceil . \]
Then it follows that
\[ a(x)2^{p(|x|)} \leq g(x) = (a(x)k^r(|x|) + b(x)) \left\lceil \frac{2^{p(|x|)}}{k^r(|x|)} \right\rceil \]
\[ < a(x)2^{p(|x|)} + b(x)\frac{2^{p(|x|)}}{k^r(|x|)} + a(x)k^r(|x|) + b(x). \]
\[ < a(x)2^{p(|x|)} + 2^{p(|x|) - q(|x|)/2} + a(x)k^r(|x|) + b(x). \]
\[ < a(x)2^{p(|x|)} + 2^{p(|x|) - q(|x|)/2}. \]
The last inequality can be achieved by choosing \( p > t + s + 2. \)

To complete the proof of Lemma 5.1 we define
\[ h(x) = f(x)2^{p(|x|)} + g(x)i(|x|), \]
where
\[ i(n) \equiv -k^r(n) \pmod{2^q(n)} \text{ and } i(n) < 2^q(n). \]
Then it follows that
\[ h(x) = a(x)k^r(|x|)2^{p(|x|)} + b(x)2^{p(|x|)} + a(x)2^{p(|x|)}i(|x|) + b'(x)i(|x|) \]
\[ = 2^{p(|x|)}a(x)(k^r(|x|) + i(|x|)) + b(x)2^{p(|x|)} + b'(x)i(|x|), \]
where
\[ k^r(n) + i(n) \equiv 0 \pmod{2^q(n)} \]
and
\[ b'(x)i(|x|) < 2^{p(|x|)} - 1. \]

\[ \square \]

Theorem 5.2 For every prime \( k, \text{ Mod}_kP \) is included in AmpMP

Proof. Let \( A \) be a set in Mod_kP and let \( r \) be a polynomial such that \( k^r(n) > 2^{2m+3}. \)
Adapting results from Toda \cite{Tod89} and Beigel, Gill and Hertrampf \cite{BeGiHe90} we can assume that there is a function \( c \) in \#P such that
\[ c(x, 0^m) \equiv \chi_A(x) \pmod{k^m}. \]
Now let \( f(x, 0^m) = c(x, 0^{\lceil m \rceil}) \cdot 2^{m+1} \). Then we have

\[
f(x, 0^m) = a(x, 0^m)2^{m+1}k^{\lceil m \rceil} + \chi_A(x)2^{m+1}
\]

where \( \chi_A(x)2^{m+1} < k^{\lceil m \rceil}/2^{m+2} \), so we can apply Lemma 5.1 to obtain a polynomial \( p \) and a function \( h \) in \#P such that

\[
h(x, 0^m) = a'(x, 0^m)2^{m+1+p(n)} + \chi_A(x)2^{m+1+p(n)} + c(x, 0^m)
\]

where \( c(x, 0^m) < 2^{p(n)} \). Remembering that \( a'(x, 0^m) \) is a multiple of \( 2^{m+1} \) we get an AmpMP characterization for \( A \).

Because Theorem 5.2 relativizes, we can state the following corollary.

**Corollary 5.3** For any \( k \), \( \text{Mod}_kP \) is low for MP and AmpMP.

**Proof.** First observe that for prime \( k \), \( \text{Mod}_kP \) is closed under Turing reductions [HeGiHe 90] and therefore is low for MP and AmpMP by Corollary 4.5 and Theorem 5.2. In the case that \( k \) is composite it follows by the representation theorem of Hertrampf [He 90] that if \( k = p^r q \) for a prime number \( p \) and \( \gcd(p, q) = 1 \), then

\[
\text{Mod}_kP \subseteq \text{Mod}_p^\text{P} \text{Mod}_p^P.
\]

Since the above lowness proof for the prime case relativizes the lowness of \( \text{Mod}_kP \) follows iterating this argument for all the prime factors of \( k \).

Corollary 5.3 together with Theorem 4.3 immediately imply the main result of this section.

**Corollary 5.4** For any \( k \) and every function \( f \) in \#P^{\text{Mod}_kP} \) there are a function \( g \in \#P \) and a polynomial \( p \) such that

\[
f(x) \equiv \lfloor g(x, 0^m)/2^{p(|x|+m)} \rfloor \pmod{2^m}.
\]

The result stated in Corollary 5.4 works also for the class \( \text{ModPH} \), a generalization of the polynomial time hierarchy that contains also \( \text{ModP} \) classes. \( \text{ModPH} \) can be considered as the polynomial time analogue to the circuit class \( \text{ACC} \).

**Definition 5.5** \( \text{ModPH} \) is the smallest family of languages containing the class \( P \) and satisfying that for any set \( A \) in \( \text{ModPH} \) the classes \( \text{NP}^A \), \( \text{co-NP}^A \) and \( \text{Mod}_kP^A \) (for any positive integer \( k \)) also are contained in \( \text{ModPH} \).

**Corollary 5.6** \( \text{ModPH} \) is contained in \( \text{AmpMP} \) and therefore is low for MP and AmpMP.

**Corollary 5.7** For all functions \( f \) in \#P^{\text{ModPH}} \) there exist a polynomial \( t \) and a function \( h \) in \#P such that

\[
\lfloor h(x, 0^m)/2^{t(|x|+m)} \rfloor \equiv f(x) \pmod{2^m}.
\]

15
6 A New Upper Bound for ACC

The methods of the preceding section relativize. It is thus not surprising that there are analogous circuit results. In this section we prove them directly.

Our main result in this section is that there is one particular symmetric function which, together with AND gates of small fan-in, can capture all of ACC: namely, the symmetric function which outputs the middle bit of the sum of the inputs.

**Definition 6.1** A MidBit gate over \( w \) inputs \( x_1, \ldots, x_w \) is a gate which outputs the value of the \( \lfloor \log(w)/2 \rfloor \)th bit in the binary representation of the number \( \sum_{i=1}^{w} x_i \).

A Mod\(_k\) gate over \( w \) inputs \( x_1, \ldots, x_w \) is defined to output 1 if \( \sum_{i=1}^{w} x_i \not\equiv 0 \pmod{k} \) and 0 otherwise.

In our simulations circuits consisting of a particular gate over small AND gates arise frequently, so we introduce the following notation.

**Definition 6.2** Let \( G \) be a Boolean gate. A family of circuits \( \{C_n\} \) is called a family of \( G^+ \) circuits if there is a polynomial \( p \) such that for each \( n \), \( C_n \) consists of a gate of type \( G \) at the root whose inputs are at most \( 2^{p(\log(n))} \) AND gates each of size at most \( p(\log(n)) \). A family of Boolean functions \( \{f_n\} \) is computable by a family of \( G^+ \) circuits \( \{C_n\} \) if for each \( n \), \( f_n(x_1, \ldots, x_n) = C_n(x_1, \ldots, x_n) \).

Note that we will always speak of families of MidBit\(^+\) or Mod\(_k^+\) circuits. Even when we refer to a MidBit\(^+\) or Mod\(_k^+\) circuit individually, it should be understood that what is meant is a member of a particular family of such circuits.

The following theorem gives the circuit analogue of Corollary 5.4. We find that for any family of functions which can be expressed as sums of Mod\(_k^+\) circuits, there is a family of low-degree polynomials whose middle bits agree with the bits of the original functions.

**Theorem 6.3** Let \( k \) be prime and let \( \{b_n\} \) be a family of functions such that there exists a polynomial \( r \) where for each \( n \), \( b_n \) is of the form

\[
b_n(x_1, \ldots, x_n) = \sum_{i=1}^{w} c_i(x_1, \ldots, x_n),
\]

where each \( c_i \) is a Mod\(_k^+\) circuit and \( w \leq r(\log(n)) \). Then for any polynomial \( t \) there are polynomials \( p \) and \( q \) and a family of polynomials \( \{h_n\} \) of degree \( p(\log(n)) \) such that for each \( n \),

\[
b_n(x_1, \ldots, x_n) \equiv [h_n(x_1, \ldots, x_n)/2^{q(\log(n))}] \pmod{2^t(\log(n))}
\]

**Proof.** Similar to the proof of Theorem 5.2. To simplify notation, unless explicitly stated, \( p, p', q, r, s, \) and \( t \) denote \( p(\log(n)), p'(\log(n)), q(\log(n)), r(\log(n)), s(\log(n)), \) and \( t(\log(n)), \)
respectively. Also denote any function \( g \) of \( x_1, ..., x_n \) as \( g(x) \). We have that each \( \text{Mod}_k^+ \) circuit \( c_i \) outputs 1 if and only if a certain sum \( \sigma_i \) of \( \text{AND} \)-gates is nonzero mod \( k \). (From an observation of Beigel, Gill and Hertrampf [BeGiHe 90], without loss of generality \( \sigma_i \) is always 0 or 1 (mod \( k \)), by Fermat's little theorem.) Note that we can think of each \( \sigma_i \) as a polynomial in \( \{x_1, ..., x_n\} \) of polylog degree. We make use of polynomials \( Q_d \) originally written down by Toda [Tod 89], and improved by Beigel and Tarui [BeTa 91]. The polynomial \( Q_d \) is of degree \( 2d - 1 \) and has the property that if \( X \not\equiv 0 \pmod{k} \) then \( Q_d(X) \equiv 1 \pmod{k^d} \), and if \( X \equiv 0 \pmod{k} \) then \( Q_d(X) \equiv 0 \pmod{k^d} \). Thus

\[
b_n(x) = \sum_{i=1}^{w} \left[ Q_d(\sigma_i) \mod k^d \right]
\]

We choose \( d = p'(\log(n)) \) where \( p' \) is a polynomial such that \( k^{p'} > 2^{r+t+2} \). Then \( b_n(x) \leq 2^r < k^{p'} \). Now the outer sum in the equation above for \( b_n \) is less than \( k^{p'} \), so the “mod” can be moved outside:

\[
b_n(x) \equiv \left[ \sum_{i=1}^{w} Q_p(\sigma_i) \right] \pmod{k^{p'}}
\]

We write

\[
f_n(x) = \sum_{i=1}^{w} Q_p(\sigma_i)
\]

Then

\[
f_n(x) = a_n(x) k^{p'} + b_n(x)
\]

for some \( a_n(x) \). Note that for some polynomial \( s \), \( f_n(x) < 2^s \). Also note that since \( \sigma_i \) is a polynomial of polylog degree, there is some polynomial \( p \) such that \( f_n \) is a polynomial of degree \( p(\log(n)) \) in the variables \( x_1, ..., x_n \). Define the degree \( p(\log(n)) \) polynomial \( h_n \) as follows:

\[
h_n(x) = i(n) \left[ 2^r/k^{p'} \right] f_n(x) + 2^r f_n(x),
\]

where \( i(n) \equiv -k^{p'} \pmod{2^r} \), following the proof of Lemma 5.1. Thus we find that \( \left[ 2^r/k^{p'} \right] f_n(x) = a_n(x) 2^r + b'_n(x) \) where \( b'_n(x) < 2^{r-1} \). Hence

\[
h_n(x) \equiv 2^r b_n(x) + i(n) b'_n(x) \pmod{2^{r+t}}
\]

where \( i(n) b'_n(x) < 2^{r-1} \). This completes the proof. \(\square\)

Corollary 6.4 Let \( k \) be prime and \( \{C_n\} \) be a family of circuits where for each \( n \), \( C_n \) consists of a \( \text{MidBit}^+ \) gate over \( \text{Mod}_k^+ \) circuits. Then \( \{C_n\} \) is computable by a family of \( \text{MidBit}^+ \) circuits.
Proof. Each $C_n$ is the MidBit of a sum $b_n$ of Mod$_k^+$ circuits. Using the previous theorem and adopting the notations of the proof, we can find a family of polylog-degree polynomials $\{h_n\}$ obeying

$$h_n(x) \equiv 2^t b_n(x) + c_n(x) \pmod{2^{t+1}} \quad (\ast)$$

for some $c_n(x) < 2^{t-1}$. Choose $t > r$. We can express $h_n \pmod{2^{t+1}}$ as a sum of non-negative terms with coefficients $< 2^{t+1-1}$. This can further be rewritten as a sum $h_n(x)$ of AND gates by replacing terms with coefficients $> 1$ by a sum of identical terms with unit coefficients. Reducing the right hand side of eq. $(\ast)$ $\pmod{2^{t+1}}$, we obtain $2^t(h_n(x) \pmod{2^t}) + c_n(x)$. Now the output bit of $C_n$ is in position $\lfloor r/2 \rfloor$ of $b_n(x)$ and is therefore in position $q + \lfloor r/2 \rfloor$ of $h_n(x)$. We can multiply the sum by repeated addition so that this is precisely the middle bit.

We now turn our attention to MidBit gates at the root and pure ACC subcircuits [Yao 90] (families of constant-depth polynomial size circuits which consist only of Mod$_m$ gates for some natural number $m$).

**Theorem 6.5** Let $\{C_n\}$ be a family of depth-d circuits consisting of a MidBit gate at the root and Mod$_m$ gates at remaining levels. Then $\{C_n\}$ is computable by a family of MidBit$^+$-circuits.

**Proof.** Beigel and Tarui [BeTa 91] have shown that a Mod$_m$ gate can be simulated by a “stratified” circuit of Mod$_{k_1}$, Mod$_{k_2}$, ..., Mod$_{k_l}$ gates where $k_1, k_2, ..., k_l$ are the prime divisors of $m$, on levels 1, 2, ..., $l$, respectively, and polylog fan-in AND gates on the lowest level. They also showed that a polylog-size AND of Mod$_k$ gates (for $k$ prime) can be switched with the Mod$_k$'s to produce a Mod$_k^+$ circuit. Using these facts, Corollary 6.4 and an inductive argument as in the proof of Lemma 6 in [BeTa 91], each layer of Mod$_{k_i}$ gates can be "absorbed" in the MidBit gate, and the resulting polylog fan-in AND gates “pushed” down to the leaves. The resulting circuit is a MidBit$^+$ circuit.

The following main theorem uses a combination of the above results, techniques of Valiant and Vazirani [ValVaz 86], Toda [Tod 89], Allender [Al 89], and Allender and Hertrampf [AlHe 90], and the technique by which we showed that BPP is low for MP. It says that circuits consisting of a MidBit gate over ACC subcircuits can be simulated by MidBit$^+$ circuits. The proof is similar to those given in Theorems 1 and 2 of [BeTa 91].

**Theorem 6.6** Let $\{C_n\}$ be a family of depth-d circuits of size $2^{\text{polylog}(n)}$ consisting of a MidBit gate at the root and Mod$_m$, AND, OR, and NOT gates at remaining levels. Then $\{C_n\}$ is computable by a family of MidBit$^+$-circuits.
Proof. Let \( C_n = 1 \) iff the \( \lfloor \log(s)/2 \rfloor \)th bit of \( S \) is 1, where \( S = \sum_{i=1}^{n} c_i \), with each subcircuit \( c_i \) consisting of AND, OR, NOT, and \( \text{Mod}_m \) gates, and without loss of generality, \( s = 2^{q(\log(n))} \) where \( q \) is a polynomial. The AND and OR gates in each \( c_i \) can be replaced by probabilistic \( \text{Mod}_m^+ \) circuits with polylogarithmically many random bits, using the techniques of [ValVaz 86], [Al 89], and [AlHe 90]. By pushing the AND-gates to the leaves, as in the preceding theorem, \( c_i \) can be simulated by a probabilistic circuit \( c'_i \) comprised of \( \text{Mod}_m \) gates and AND gates of polylog fan-in at the lowest level, so that \( \Pr(c'_i \neq c_i) \leq 2^{-q(\log(n)) - 2} \). It is possible to simulate \( c_i \) with such a \( c'_i \) using \( t(\log(n)) \) bits where \( t \) is a polynomial such that \( t > q + 2 \). Let \( c''_i \) denote the sum of \( c'_i \) over all possible settings of the random bits of \( c'_i \), and let \( S' := \sum_{i=1}^{n} (c''_i + 2^{t(\log(n)) - q(\log(n)) - 2}) \). One can show that \( S' = 2^{t(\log(n))} + r \) where \( r < 2^{t(\log(n))} \). The output of the desired MidBit+ circuit is the bit in position \( \lfloor \log(s)/2 \rfloor + t(\log(n)) \) of \( S' \). \( \square \)
