Recently, Cai and Sivakumar [CS95] settled a conjecture of Hartmanis [Har78], showing that unless \( P = \text{LOGSPACE} \), no sparse set can be hard for \( P \) under logspace many-one reductions. In this note, we settle another conjecture of Hartmanis about sparse hard sets for nondeterministic logspace (NL). We show that if there is a sparse set \( S \) that is hard for \( NL \) under logspace many-one reductions, then \( NL = \text{DLOGSPACE} \).

In what follows, we abbreviate NL by \( NL \) and DLOGSPACE by \( L \). The proof builds on the techniques of Cai and Sivakumar [CS95]. As in the case of reductions from \( P \) to sparse sets, we will describe a parallel algorithm for an \( NL \)-complete problem. The parallel algorithm can be implemented by a polynomial-size, log-depth circuit that makes polynomially many parallel calls to the reduction from \( NL \) to the sparse set \( S \). It implies the stronger result that if \( NL \) has a sparse hard set under \( NC^1 \) many-one reductions, then \( NL = NC^1 \).

Our result improves the result of Cai, Naik and Sivakumar [CNS95], who show that if there is a sparse set \( S \) that is hard for \( NL \) under logspace many-one reductions, then \( NL = \text{Randomized LOGSPACE} \) (where the randomized logspace machine is given two-way access to a random tape). Their proof makes use of a randomized reduction from \( s-t \) connectivity to the so-called "unique \( s-t \) connectivity" problem. Given a graph \( G \) and a pair of vertices \( s, t \), this reduction produces a polynomial number of graphs \( G_1, \ldots, G_k \) of polynomial size, together with distinguished vertex-pairs \((s_1, t_1), \ldots, (s_k, t_k)\), that satisfy the following conditions. If there is no path from \( s \) to \( t \) in \( G \), then no \( G_i \) has a path from \( s_i \) to \( t_i \); if there is a path from \( s \) to \( t \) in \( G \), then with high probability, at least one of the \( G_i \)'s has a unique path from \( s_i \) to \( t_i \). This reduction is due to Avi Wigderson [Wig94], and it exploits the "isolation lemma" of Mulmuley, Vazirani and Vazirani [MVV87]. In contrast, the proof given below eliminates the need for the unique witness property; instead, it uses the famous Immerman–Szelepcsenyi result that \( NL = \text{co-NL} \) [Imm88, Sze87].

First we note that the \( s-t \) connectivity problem for directed acyclic graphs (DAG-STCON) is complete for \( NL \) under logspace- (or even \( NC^1 \)-) computable many-one reduc-

tions. Wlog., we may also assume that all instances of DAG-STCON are labeled and layered graphs, that is, graphs where all edges go from lower-numbered vertices to higher-numbered vertices.

It is known that if \( m \) is of the form \( 2 \cdot 3^\ell \) for some integer \( \ell \geq 0 \), the polynomial \( x^m + x^{m/2} + 1 \) is an irreducible polynomial of degree \( m \) over \( GF(2) \) [vl.91]. In the following, by a finite field \( GF(2^m) \), where \( m = 2 \cdot 3^\ell \), we refer explicitly to the field \( Z_2[x]/(x^m + x^{m/2} + 1) \). We define the language \( B \) that consists of tuples of the form \( (G, s, t, 1^m, \alpha, \beta) \), where:

1. \( G = (V, E) \) is a directed, layered acyclic graph on \( n \) vertices (hence \( G \) has at most \( k = \binom{n}{2} \) edges, and the adjacency matrix \( A \) of \( G \) is upper-triangular).
2. \( s \) and \( t \) are vertices in \( G \).
3. \( m \) is of the form \( 2 \cdot 3^\ell \) for some integer \( \ell \geq 0 \).
4. \( \alpha, \beta \in GF(2^m) \)
5. \( \sum_{i=1}^k \alpha_i X_{u_i, v_i} = \beta \), where for \( 1 \leq i \leq k \), \( 1 \leq u_i \leq v_i \leq n \), \((u_i, v_i)\) denotes the \( i \)-th edge in \( G \), and \( X_{u_i, v_i} \) is a boolean variable that is 1 if and only if there is a path from \( u_i \) to \( t \) whose first step is the edge \((u_i, v_i)\).

We begin by observing that the language \( B \) is complete for NL. DAG-STCON easily reduces to \( B \), hence \( B \) is NL-hard. Moreover, testing whether \( (G, s, t, 1^m, \alpha, \beta) \in B \) requires computing polynomially many predicates \( X_{uv} \). The language \( Z = \{(G, s, t, u, v) \mid X_{uv} = 1\} \) is in NL, and since NL = co-NL, its complement \( Z^c \) is also in NL. The nondeterministic logspace machines for \( Z \) and \( Z^c \) can be used to build a nondeterministic logspace machine that computes \( X_{uv} \) in the following strong sense: every computation either outputs the correct value of \( X_{uv} \) or aborts in a "DON'T KNOW" state, and at least one computation is guaranteed to output the correct value of \( X_{uv} \). Using this, it is easy to build a nondeterministic logspace machine for the language \( B \) that computes \( X_{uv} \) for all \((u, v) \in E\), and accepts \((G, s, t, 1^m, \alpha, \beta) \) if and only if \( \sum_{i=1}^k \alpha_i X_{u_i, v_i} = \beta \). In other words, \( B \in NL \).

By hypothesis, \( B \leq_m S \). Let \( f \) denote the (logspace- or NC\(^1\)-computable) function that reduces \( B \) to \( S \). We will show how to solve DAG-STCON using \( f \) as an oracle. Fix \( G, s \) and \( t \). Using the same ideas as in the case of reduction from P to S, we can set up equations and solve for the variables \( X_{uv} \) for all \((u, v) \in V, u \leq v\). Recall that this scheme produces a polynomial number of sets of solutions, where at least one set of solutions is guaranteed to be correct. It remains to show how to verify the correctness of solutions. Each set of solutions for the \( X_{uv} \)'s can be assumed to be in the form of a matrix \( X \) of the same dimensions as \( A \), the adjacency matrix of \( G \). By its definition, \( X_{uv} \) is 1 only if \((u, v) \in E\). Therefore, for each candidate set of solutions, we will first verify that the condition \( X_{uv} \leq A(u, v) \) holds for all \((u, v) \in V\). It is easy to see that this test can be performed simultaneously on all sets of solutions by a polynomial-size, log-depth circuit. Note that since \( A \) is a strictly upper-triangular matrix, every \( X \) that passes this test is strictly upper-triangular.

For every \( u \in V \), we first compute the boolean variable \( X_u \) that is 1 if and only if \( u = t \) or there exists some \( v \) such that \( X_{uv} = 1 \). In matrix terms, \( X_u = 1 \) if and only if \( u = t \) or
there is at least one 1 in the row corresponding to \( u \) in the matrix \( X \). This computation can be easily done by a polynomial-size, log-depth circuit, since it only requires computing the OR of \( n \) bits. Next we perform the following local consistency check: for every \( u \) such that \( X_u = 1 \) and for every \( v \) such that \( X_{uv} = 1 \), verify that \( X_v = 1 \). This test ensures that if \( X \) promises a path from \( u \) to \( t \) with \( v \) as the first vertex, then indeed \( X \) also promises some path from \( v \) to \( t \). Notice that the latter path cannot include the vertex \( u \) since \( G \) is acyclic. This is important because, otherwise, it is possible that \( X \) passes this test by setting \( X_{uv} = X_{vu} = 1 \) even though \( t \) is reachable from neither of \( u \) and \( v \). It is amply clear that the local consistency check can be performed by a polynomial-size log-depth circuit.

Finally we argue that there exists a path from \( s \) to \( t \) if and only if some set of solutions \( X \) has \( X_s = 1 \). Clearly, if there is a path from \( s \) to \( t \) then the correct solution for \( X \) will pass all the tests and have \( X_s = 1 \).

Next we claim that if \( X \) passes all the tests, \( X_z = 0 \) for all \( z > t \). In particular, if \( s > t \) but \( X_s = 1 \) (incorrectly), the local test will catch this. The claim is vacuous if \( t \) is the last vertex. Otherwise, we prove the claim by induction, starting from the last vertex. By the first test against the adjacency matrix and since the graph is layered, the base case is clear. Assume inductively that \( X_z = 0 \) for all \( t < z_0 < z \). If \( X_{z_0} = 1 \), then by the definition of \( X_{z_0} \), for some \( z > z_0 \), \( X_{z_0} = 1 \). However, it then fails the local test, since \( X_s = 0 \).

To complete the proof, we argue that whenever \( X_u = 1 \) for some \( u \leq t \), there is a path from \( u \) to \( t \). The base case, namely \( u = t \), is trivial. Suppose \( X_u = 1 \) for some \( u < t \). By definition, there is a vertex \( v \) such that \( X_{uv} = 1 \) and \( X_v = 1 \). The first test ensures that there is an edge \((u, v)\). If \( v = t \), it is clear that there is a path from \( u \) to \( t \). If \( v < t \), by the inductive hypothesis, there is a path from \( v \) to \( t \), which, together with the edge \((u, v)\), gives a path from \( u \) to \( t \).

**Theorem 1** If there is a sparse hard set for NL under logspace many-one reductions, then \( \text{NL} = \text{L} \).

**Theorem 2** If there is a sparse hard set for NL under many-one reductions computable in logspace-uniform \( \text{NC}^1 \), then \( \text{NL} = \text{logspace-uniform \text{NC}^1} \).

Using the techniques of Cai, Naik, and Sivakumar [CNS95], the following can be shown:

**Corollary 3** If there is a sparse hard set for NL under logspace-computable randomized many-one reductions with two-sided error, then \( \text{NL} = \text{RL} \), where \( \text{RL} \) is the class of languages accepted by logspace Turing machines with two-way access to the random tape.

**Corollary 4** If there is a sparse hard set for NL under randomized many-one reductions with two-sided error that are computable in logspace-uniform \( \text{NC}^1 \), then \( \text{NL} = \text{logspace-uniform \text{RNC}^1} \).
Finally, exploiting an idea of Van Melkebeek [Mel95], the following can be shown; similar results hold for randomized bounded truth-table reductions:

**Theorem 5** If there is a sparse hard set for NL under bounded truth-table reductions computable in logspace, then NL = L.

**Theorem 6** If there is a sparse hard set for NL under bounded truth-table reductions computable in logspace-uniform NC¹, then NL equals logspace-uniform NC¹.
