Testing membership in unitriangular matrix groups
Preliminary draft

Abstract
We present an algorithm that, given a subgroup $G$ of the group of the upper triangular matrices with rational entries by a set of generators, computes generators of the lower central series of $G$. As an application, we show that the constructive membership problem in $G$ can be performed in polynomial time. This draft is intended to be part of a larger project investigating the complexity of computational problems in finitely generated linear groups.

1 Introduction

Polynomial time algorithms for computational problems in some classes of matrix groups over algebraic number fields have been recently obtained. The constructive membership problem in a linear group $G$ given by a finite set of generators has been shown to be soluble in polynomial time in the one-dimensional case by Ge [Ge1, Ge2] in the abelian case by Cai, Lipton, Zalcstein [CLZ] Babai, Beals, Cai, Ivanyos, and Luks [BBCIL] in the abelian-by-finite case by Beals [Be]. Beals [Be] also presents a polynomial time algorithm that decides whether $G$ is soluble-by-finite (nilpotent-by-finite, or abelian-by-finite) and if this is the case then computes normal generators of a soluble (nilpotent, abelian respectively) normal subgroup of finite index.

Ostheimer [Os] has developed similar algorithms independently. In the polycyclic-by-finite case based on computing a polycyclic presentation of the maximal unipotent normal subgroup, she also presents (without complexity analysis) an algorithm for the membership problem.

Most difficulties in analyzing complexity arise in iterative computations in unipotent groups. A polynomial time algorithm to compute the lower central series of a unipotent group. The author is convinced that the result leads to a polynomial time algorithm for the constructive membership problem in the finite-by-polycyclic case. There is also some hope that the method can be useful in studying the complexity of the membership problem in the soluble-by-finite case.

Since this draft is intended to be a fragment of larger work, the detailed introduction is omitted. The reader is referred to [CLZ] [BBCIL] or [Be] for background and basic concepts. We use very elementary tools form the theory of nilpotent Lie groups and algebras. We use very elementary tools form the theory of nilpotent Lie groups and algebras (c.f. [FV] and [Po]).

2 The algorithm

Assume that we are given $G \leq UT_n(\mathbb{Q})$ by a generating system $S = \{s_1, \ldots, s_m\} \subseteq UT_n(\mathbb{Q})$, where $UT_n$ stands for group of the upper triangular unipotent matrices. Let $N_n(\mathbb{Q})$ denote the set of upper triangular nilpotent matrices. $N_n(\mathbb{Q})$ is in fact a nilpotent (associative) subalgebra in $M_n(\mathbb{Q})$. It follows that $N_n(\mathbb{Q})$ is a nilpotent Lie algebra with the bracket operator $[x, y] = xy - yx$.

Using elementary methods from Lie theory, we compute the lower central series of $G$. For convenience of the reader we attempt to be more or less self-contained. In our case case we do not have to use topological arguments, and we can perform computations over the rationals. The only tools used are the mapping $\exp$ its inverse log defined by formal power series and the Campbell-Hausdorff series reflecting the most important properties. For $x \in N_n(\mathbb{Q})$,

$$\exp x = \sum_{i=0}^{\infty} \frac{1}{i!} x^i = \sum_{i=0}^{n-1} \frac{1}{i!} x^i,$$

and for $x \in UT_n(\mathbb{Q})$

$$\exp x = \sum_{i=1}^{\infty} \frac{(-1)^{i-1}}{i} (x - 1)^i = \sum_{i=1}^{n-1} \frac{(-1)^{i-1}}{i} (x - 1)^i.$$

For every $x, y \in UT_n(\mathbb{Q})$ the log of $xy$ can be expressed by the Campbell-Hausdorff series

$$\log(xy) = \log x + \log y + \frac{1}{2} [\log x, \log y] + \sum_{i=3}^{n-1} \frac{1}{i!} \sum_{i=1}^{n-i} \frac{(-1)^{i-1}}{i} (x - 1)^i.$$

where for every $i$, $D_i(u, v)$ is a homogeneous Lie polynomial over $\mathbb{Q}$ in $u$ and $v$ of degree $i$ (the Dynkin polynomials). Recall that a Lie monomial in $u, v$ of
degree \(i > 1\) is a term \([[[u_1, u_2, \ldots, u_i]]]\), where \(u_1, u_2, \ldots, u_i \in \{u, v\}\). (The unique Lie monomial of degree 1 is \(x + y\).) A homogeneous Lie polynomial over \(Q\) of degree \(i\) is a \(Q\)-linear combination of Lie monomials of degree \(i\).

We start with computing (a basis of) \(L_1 = L = L(G)\), the rational Lie algebra generated by \(\log S = \{\log s_1, \ldots, \log s_n\}\). By the Campbell-Hausdorff formula \(L\) is in fact the Lie algebra over \(Q\) generated by \(\log G = \{\log g | g \in G\}\). We also compute \(L_2 = [L, L], \ldots, L_r = [L_{r-1}, L_1], L_{r+1} = [L_r, L_1] = 0\) the lower central series of \(L_1\) (in the traditional notation \(L_i = L_i^{-1}\)). We use this indexing to express the correspondence with degrees of Lie polynomials.) For \(i = 1, \ldots, r\), let \(\mathcal{G}_i = \{\exp x | x \in L_i\}\). Note that \(\mathcal{G} = \mathcal{G}_1\) consists of the rational points of the (real or complex) Lie group corresponding to the (real or complex) Lie algebra obtained from \(L\) by extending scalars. What follows is the well-known correspondence between the central series of Lie groups and their Lie algebras.

Again by the C-H formula \(\mathcal{G}_i \leq UT_i(Q)\) and we have that \(\log: \mathcal{G}_i \to L\) is a bijection (the inverse of \(\exp\)). For the logarithm of products and commutators we have:

\[
\log(xy) = \log x + \log y + \frac{1}{2} [\log x, \log y] + \text{commutators of degree } \geq 3
\]

and

\[
\log(x^{-1}y^{-1}xy) = [\log x, \log y] + \text{commutators of degree } \geq 3
\]

It follows that if \(x \in \mathcal{G}_i\) and \(y \in \mathcal{G}_j\) then

\[
\log(xy) \equiv \log(x) + \log(y) \pmod{L_{i+j}}
\]

and

\[
\log(x^{-1}y^{-1}xy) \equiv [\log x, \log y] \pmod{L_{i+j} + \text{min}(i, j)}
\]

In particular, the restriction of \(\log\) to \(\mathcal{G}_i\) induces an isomorphism \(\mathcal{G}_i/\mathcal{G}_{i+1} \cong L_i/L_{i+1}\), the latter is understood as the additive group. Also, it is easy to see that \(\mathcal{G}_{i+1} = [\mathcal{G}_i, \mathcal{G}_i]\). In other words, \(\mathcal{G}_1, \mathcal{G}_2, \ldots, \mathcal{G}_r\) is the lower central series of \(\mathcal{G}\) (in the traditional notation \(\mathcal{G}_1 = G^{-1}\)).

Let \(G_i = G \cap \mathcal{G}_i\). It is obvious that \([G_i, G_i] \leq G_{i+1}\).

Now \(S\) generates \(G\), and \(\log S\) generates \(L\); therefore \(\log S\) generates a lattice of full rank in the vector space \(L/L_2\). By lifting back a basis of this lattice to \(G\) we find \(S_1 \subseteq G\) such that \(S_1 (\text{modulo } G_2)\) is a basis of the group \(G\mathcal{G}_2/\mathcal{G}_2 \cong G/G_2\). Inductively assume that the set \(S_i \subseteq G_i\) is such that \(S_i\) is a basis of the factor group \(G_i/\mathcal{G}_{i+1} \cong G_i/G_{i+1}\), and \(\log S_i\) is a \(Q\)-basis of the vector space \(L_i/L_{i+1}\). It follows that \(L_{i+1} = [L_{i+1}, \text{span}(\log S_i), L_2 + \text{span}(\log S_i)] \subseteq L_{i+2} + \text{span}(\log S_i, \log S_i)\), therefore \(\log S_i\) generates a lattice of full rank in \(L_{i+1}/L_{i+2}\). Lifting a basis of this lattice to \(G\) we obtain a basis \(S_{i+1} \subseteq [G_i, G_i]\) of the factor group \(G_{i+1}/G_{i+2} \cong G_{i+1}/G_{i+2}\), such that \(\log S_{i+1}\) is a vector space basis of \(G_{i+1}/G_{i+2}\). This argument also shows that \(G = G_1 > G_2 > \ldots\) is in fact the lower central series of \(G\).
Finally, we obtain a generating system $S_1 \cup S_2 \cup \ldots \cup S_r$ of $G$ such that for every $1 \leq i \leq r$, $S_i \cup \ldots \cup S_r$ is a generating system of $G_i$ and $S_i$ is a basis of the free abelian group $G_i/G_{i+1}$.

To keep the size of the basis elements polynomial, in each round, we take $S_i$ such that $\log S_i$ is a reduced basis (in the sense of [LLL]) of the lattice $\log G_i + L_{i+1}/L_{i+1}$. To prove that it works we have to show that the lattice $\log G_i + L_{i+1}/L_{i+1}$ is of polynomial size (i.e., admits a basis of polynomial size). It is enough to prove that $\log G_i + L_{i+1}/L_{i+1}$ is in a "sandwich" of lattices of polynomial size - there exists lattices $M_i$ and $N_i$ of polynomial size in $L_i/L_{i+1}$ such that $M_i \subseteq \log G_i + L_{i+1}/L_{i+1} \subseteq N_i$.

The lower bound can be obtained from a simplification of the algorithm to compute $S_i$. Let $\tilde{S}_1 = S_1$, and in each step we choose a maximal linearly independent set from $\log[\tilde{S}_i, S_i]$ modulo $L_{i+2}$. It can be easily shown by induction that for every $i$, $M_i = \log \tilde{S}_i + L_{i+1}$ is a sublattice of full rank of $\log G_i + L_{i+1}/L_{i+1}$. On the other hand, every element of $S_i$ is an iterated commutator of $i$ elements from $S_1$, therefore must be of polynomial size.

The upper bound is not difficult either. Conjugating by an appropriate diagonal matrix we may achieve the situation where $G \leq UT_n(n^!Z)$, i.e. the elements of $S$ are upper triangular unipotent matrices with integer entries divisible by $n^!$. Then for every $g \in G$ we have that $\log g$ is in the lattice $H$ of the upper triangular nilpotent matrices with integer entries, therefore $G_i + L_{i+1}/L_{i+1}$ is a sublattice of the lattice $N_i = H + L_{i+1} \cap L_i/L_{i+1}$.

Note that there is an alternative way to find generators in $G_iG_{i+1}/G_{i+1}$. Namely if $S_i$ is set of generators of $G_iG_{i+1}/G_{i+1}$, then from $[S_i, S_{i+1}]$ we can choose a set of generators of $G_iG_{i+2}/G_{i+2}$. The bounds on the lattice guarantee that we can always choose a set of polynomially many elements. (If we already have a set of full rank then adding a new element increases the discriminant by a multiplicative factor.)

We have proved

**Theorem 1** Given a finitely generated $G \leq UT_n(Q)$ by generators, we can find in polynomial time $S_1, S_2, \ldots, S_r \subseteq G$ such that for every $i$, $S_i$ (modulo $G^i$) is a basis of the factor group $G^{i-1}/G^i$, where $G^{i-1}$ is the $i$th element of the lower central series of $G$.

**Corollary 2** Given a finitely generated $G \leq UT_n(Q)$ by a set of generator $S$, and an element $x \in UT_n(Q)$, we can decide in polynomial time whether $x \in G$, and if $x \in G$ we can find in polynomial time an expression (straight line program) of $x$ in terms of $S$.

**Proof.** We start with testing whether $x \in G$. If it is, $\log x + L_2$ can be written as a unique linear combination of the elements $\log s_j + L_2$ where $s_j$ are the elements of $S_1$. The coefficients are integers if and only if $sG_2 \subseteq G_2G_2$. If the coefficients are integers, we divide $x$ by the product of appropriate powers of
and obtain an element (denoted again by $x$) of $G_2$, and we can proceed with $G_2, L_2, G_2, \ldots$ By Cramer's rule it is easy to see that the sizes are polynomial.
